ABSTRACT

Cryptosporidium spp. and Giardia duodenalis are 2 protozoan parasites that affect humans and a wide range of domestic and wild animals. These parasites are a major cause of diarrheal disease in humans and animals worldwide, causing high morbidity in their hosts, in immunocompromised hosts and children, they can lead to death. In order to assess the prevalence of these protozoans among population in the northern part of Delta and the risk of human infection, 330 people (175 females and 155 males) with or without symptoms who attended a Health Care Center were parasitologically studied. The purpose of this study was to assess the frequency of Cryptosporidium spp. and Giardia spp. in the northern part of Delta (Damietta governorate) and the risk of human infection of these protozoa related to personal data, socio-cultural and environmental characteristics, and the presence of symptoms/signs among a rural and urban population. Of the surveyed population (330), 3.6% were infected with Cryptosporidium spp. only or 24.2% with Giardia spp. and 2.4% were infected with both protozoa. The frequency of infection according to sex; 2.7% of males were infected and 0.9% of females by Cryptosporidium spp. 12.7% and 11.5% by Giardia spp. and 1.5% and 0.9% by both parasites, respectively. Cryptosporidium spp. and Giardia spp. was frequent in children (under 12 year) than adults in both sexes, however, Cryptosporidum infections were most frequently diagnosed in children less than 12 years old and prevalence decreased with age. The prevalences of these protozoa in this community are lower than those reported by other studies, which is probably associated with the low density of the studied population. Statistical analysis revealed that a male sex, children, loss of weight, improper waste disposal, diarrhea and abdominal pain were correlated with the presence of these parasites, which indicate the importance of these factors in rural communities.

Keywords: Cryptosporidium spp., Giardia spp, epidemiology, rural and urban community, North Delta, Damietta Governorate.

INTRODUCTION

Cryptosporidium spp. and Giardia duodenalis are 2 protozoan parasites that affect humans and a wide range of domestic and wild animals [1-3]. These parasites are a major cause of diarrheal disease in humans and animals worldwide, causing high morbidity in their hosts, and in immunocompromised hosts, they can lead to death. The transmission of these 2 parasites is sustained by zoonotic (animal to human) and anthropoontic (human to human) cycles where several species and genotypes are enrolled [3-5]. The protozoan flagellate Giardia lamblia shares several epidemiologic characteristics with C. parvum. Both organisms are water-borne and this route has been the cause of like C. parvum, G. lamblia is a cause of childhood diarrhea and may be transmitted by close-contact and is often associated with epidemics of diarrhea in day care facilities. 16 The prevalence of both G. lamblia and C. parvum is generally higher among very young children and this may be
related to more efficient fecal-oral transmission of the infective stages or enhanced susceptibility due to lack of immunity. While the prevalence of cryptosporidiosis and giardiasis is well documented in patients and children with human immunodeficiency virus (HIV) and AIDS, data are not widely available on the cross-sectional distribution of these infections. Water-borne outbreaks of infections with the parasites have highlighted the fact that morbidity may occur outside of these focus groups in endemic areas. The infected hosts shed in the environment a large number of these transmissive and infective stages, contributing to an increase of environmental contamination. Cysts and oocysts not only remain infective for long periods in environment but are also resistant to the conventional treatment processes of water, representing a serious problem of public health [2,8-12]. This problem is also potentiated by the fact that the number of parasites required to induce infection is small, i.e., infectious dose of 83-123 oocysts for Cryptosporidium spp. and 19-50 cysts for G. duodenalis [1,13]. Intestinal infections caused by Cryptosporidium and Giardia spp. are associated to climatic factors, basic sanitary conditions, and sociocultural characteristics [7]. Traditionally, the prevalence of these infections was considered a "stable endemic characteristic" resulting from the dynamics of repeated re-infection [1]. (According to Atías[1] and[7], the frequency at which repeated infection occurs in a population depends on the "infection pressure" and host susceptibility. "Infection pressure" is defined as the number of host exposures at a given location over a certain period of time. The factors involved in "infection pressure" are of two types: environmental and socio-economic, which are intimately linked since the environment has a certain influence on the socio-economic conditions of a population and human activities also affect the environment [15]. Environmental conditions (e.g. temperature, humidity, wind, soil) and socio-economic factors are responsible for spreading and for developing infectious forms of Cryptosporidium and Giardia spp., and for polluting the environment with these agents. Giardiasis is a cosmopolitan zoonotic infection, and predominates in mild humid climates. According to Crompton [4], two hundred million are infected with Giardia spp. worldwide. And, 15% of the rural population in Latin America is estimated to be infected with these parasites; with a higher prevalence among children [1]. In addition, the infection prevalence is lower in the upper strata of the population, and increases in day care centers attended by the children of poorer families [6]. On the other hand, Cryptosporidium is an intestinal parasite that infects both in humans and animals. Infection with Cryptosporidium spp. was reported in immunocompromised, as well as immunecompetent, children and adults [1] and in animals [15]. The disease occurs in most countries including Arabian countries [19], USA [9] and Egypt [1, 8, 9, 15&19] It also has a higher prevalence in tropical regions, reaching infection levels of 20-50%, especially in rural areas [9]. Moreover, both protozoan infections are associated with non-specific gastrointestinal symptoms [10] diarrhea and weight loss. [3].

The purpose of this study was to assess the frequency of Giardia spp. and Cryptosporidium in the northern part of Delta and the risk of human infection of these proto zoa related to personal data, socio-cultural and environmental characteristics, and the presence of symptoms/signs among a rural and urban population.

**Subjects, Materials and Methods**

**Study area**
North Delta, Damietta Governorate, Damietta city representing urban area and Kafr saad villages representing rural area (10km apart from Damietta). Damietta is a governorate situated in the north region of Delta, which lies in northeast Egypt some 200 km from the capital city, Cairo (Fig. 1). Million five hundred thousand people reside in an area of 589 km² (991,687 inhabit rural areas). The town has a commercial downtown or "urban region", surrounded by a rural area.

Fig. 1: Geographical location of North Delta of Egypt.

Selected population
The study extended from January 2010 to January 2011, stool samples were referred to Department of parasitology, Faculty of medicine(Damietta), Al-Azhar University, Egypt Total 330 people (175 females and 155 males), with or without symptoms, who attended a Health Care Center were studied. Of these, 191 people lived in an urban area (UA) (57.4%) and 139 in a rural area (RA) (42.6%); 239 were under 12 years old, and 134 lived in the UA. Each individual was surveyed for personal, environmental and socio-cultural data. Personal information - age, sex, and place of residence - was collected, as was socio-cultural and environmental information, garbage disposal (open pit, burning, burying or city garbage collection), water supply (running water, home pump, community pump), tap (inside/outside, public), body waste disposal (sewage, well with a chamber, cesspool, or latrine), overcrowding (presence or absence, presence was defined as more than three people sleeping to a room), and house flooding (never, sometimes, frequent). In addition, subjects were asked about the presence or absence of the following symptoms/signs: anal itching, abdominal pain, sleeping disorders, diarrhea, vomiting, appetite loss, weakness, and weight lost.

Parasite analysis
A serial parasitological analysis was performed, consisting of stool sampling from a daily spontaneous bowel movement, sample were stored in a jar containing 5% formaldehyde. To detect *Giardia* spp. and *Cryptosporidium*, the samples were processed and subjected to direct wet smear method and Sheather's sugar flotation and acid-ether sedimentation techniques Technique [22]. Processed pellets were stained with lugol and modified Ziehl-Neelsen acid fast stain and observed under a microscope.

Statistical analysis
Significant associations were determined using the chi square test and Fisher's test. Socio-cultural and environmental characteristics, symptoms, age, and sex were used as (independent) explanatory variables. SPSS software, version 11.5 was used throughout.

Results
Fig (1) show detecting Cyst of *G. lamblia* in iodine preparation (A) and *Cryptosporidium*
Sex, age, and place of residence in the analyzed population are shown in Table 1. In the studied population, 3\% (10/330) of subjects were infected with *Cryptosporidium* spp. only, 22.7\% (75/330) with *Giardia* spp. only and 4.5\% (15/330) were infected with both protozoa. Regarding *Cryptosporidium* spp. infection, 5.6\% (9/158) of males were infected and 1.7\% (3/172) of females, similarly for *Giardia* spp., 26.5\% (42/158) of males were infected and 22\% (38/172) of females, and 3.1\% (5/158) and 2.9\% (5/172) were infected with both protozoa. These apparent differences between the sexes were not significant.

The prevalence of *Cryptosporidium* spp. was 3.1\% (6/191) in the UA and 4.0\% (8/193) in the RA. *Giardia* spp. prevalence was similar in both areas, i.e., 23.5\% (45/191) in the UA and 21.5\% (30/139) in the RA. Of the 10 people parasitized by both protozoa, 5 (2.6\%) lived in the UA and 5 (3.5\%) in the RA. Distributions according age, sex, and place of residence are shown in Table 2. Analysis of the age distributions of both parasites in the populations revealed that the frequency of *Cryptosporidium* spp. infection was highest among those aged 2 to 7 years, peaking at 4 years of age. On the other hand, *Giardia* spp. less age dependent and was found to be present in subjects up to 70 years old, peaking between the ages 4 and 12. When the data of both parasite infections were evaluated, mean age for *Cryptosporidium* spp. infection was 7 years and for *Giardia* spp. infection 24 to 35 years.

Association between clinical manifestation of Cryptosporidium and Giardia lamblia infection with socio-cultural and environmental data of the study population. When these variables and the presence/absence of symptoms/signs were correlated with parasite frequency are shown in Table 3.

DISCUSSION

Intestinal parasites are very common in developing countries and Cryptosporidium and Giardia have been revealed as one of the most common parasites. Cryptosporidium sp. is a primary pathogen causing acute diarrhea and the most evident symptom of cryptosporidiosis is diarrhea. Non-specific signs such as dehydration, fever, anorexia, weakness, and progressive loss of weight may be accompanied. Diarrhea is usually self-limiting in immunocompetent humans; however, it can be life-threatening in children and immunocompromised humans. Its prevalence varies according to different regions [5]. In developed countries, massive
Cryptosporidium food-borne and water-borne outbreaks have been reported, while in developing countries, Cryptosporidium is associated with significant morbidity and mortality, especially among infants and children[27]. In Egypt, human cryptosporidiosis been reported with variable prevalence rates by [1, 8, 9, 15&19]. The overall frequency of Giardia spp. infection found in the present study was higher than those reported for similar studies in Italy (3.5%,[13]); but it is lower than those reported in Venezuela (28%,[16]), Chennai (26%, [11]), Pakistan (28.78%, in [23]), and in Brazil (27.4%,[18]). Similar results were obtained in studies carried out in Thailand (5.3%,[28]), and Spain (5.05%,[20]). Other studies carried out in Argentina have reported higher rates of these parasites. Thus, Gamboa et al. [12] reported 34% for a shantytown, Guignard et al. [14] 23% in a population living in temporary homes, and Borda et al. [4] who reported 29% in shantytown. As regards studies carried out on the prevalence of Cryptosporidium in similar populations in other countries, our results are higher than those published by Wang et al. [29] in China (1% and 3.96%), Windsor et al. [31] in the United Kingdom (2.9%),[6] in Spain (1.5%),[28] in Thailand (0.8%), and [17] in Venezuela (1.6%). Percentages similar to those of the present study were found by [26] in members of the Thai Army and their families (4.1%). As regards data collected in Argentina, [12]report 48% in a shantytown, [14] 44.4% among those living in temporary homes, [21] 65.8% among a suburban population, and [24] 24.6%. A compared with previous Argentinean figure our prevalence rates for both parasites are notably lower. This may be due to the rural nature of our study population, and socio-economic, cultural, and demographic (fewer inhabitants per square km) differences, which would be expected reduce infection pressure. Regarding sex, these protozoa were markedly more prevalent among males in the UA group, with an outstanding higher frequency in under 12-year olds. This is probably because the direct transmission of these parasites is related to higher population densities in the urban area, and because of the different hygiene habits of males and females in the same setting, which is reflected by the relatively low/high prevalence observed in the infant population. The category less than 12 years old was a risk factor for this infection. These results agree with the development of acquired immunity to both parasites consequent to repeated infections in childhood [10]. Of the socio-cultural and environmental variables studied, frequent flooding, dirt floor inside the home, cardboard/tin homes, and body waste disposal by latrine were associated with the prevalence of these parasites, and/or blastocystis. Therefore, the presence of these conditions could be used to estimate the risk of infection by these parasites. These data reinforce the existing strong relation between deficient sanitary conditions and intestinal parasitism, as has been mentioned by several Argentinean authors[4,12&24]. Several authors reported a correlation between diarrhea, abdominal pain, flatulence, itching, vomiting, or appetite loss, and the presence of both protozoan infections[6&17]. In this study only abdominal pain was found to be significantly associated with the presence of Cryptosporidium and/or Giardia spp. The present study is one of the first to associate the prevalence of Giardia spp. and/or Cryptosporidium with socio-cultural and environmental conditions, and with the clinical features of a North Delta population. We conclude that the low population density of the area studied substantially creates a lower infection pressure, and explains the lower infection prevalence’s of the present study. The risk factors for acquiring G. spp
and C. spp in Damietta are apparently similar and this is reflected in their age-prevalence profiles. Alternately, age-related acquisition of immunity to infection or loss of infection may be different for the parasites and this may contribute to the observed patterns that most infections with the parasites were in children, and clinical diagnosis was not an accurate indicator of infection. Factors such as malnutrition and bottle feeding as seen in some Rural areas may be important in determining the epidemiology of the infections in North Delta. The prevalence of G. spp. infections increased with age and this may be reflective of the increasing exposure as children attend schools and day-care facilities. Perhaps feeding or infection from untreated water may be more important for transmission of C. spp in young children.
